THE INVESTMENT FUNDS SYSTEM RECONSIDERED

1   Introduction

Over the past decades, governments of most indus-
trialized countries have attempted to promote capi-
tal formation by enacting various schemes of in-
vestment incentives. A widely publicized scheme is
the investment funds system (IF), set up as a com-
ponent of the Swedish corporation income tax.

The original idea behind the IF system was to in-
duce firms to reserve profits during boom years and
use them for investments during subsequent reces-
sions. In its present form, the system began in
1955, but funds were not released until 1958. Since
the end of the 1960's, funds have been released
more and more frequently. In particular, efforts
during the 1970's to stimulate industrial growth
meant that firms could use the IF system almost
continuously for new investments.

Investments "financed" through releases of invest-
ment funds receive a substantial subsidy, compar-
able to that obtained from the use of free depreci-
ation. This led researchers to conclude that re-
leases of investment funds will cause a sharp re-
duction in the cost of capital providing an induce-
ment to invest[1]. In a recent article Bergström
and Södersten (1984) question this "conventional

----

[1] See for example Praski (1978), Kanis (1979),
Bergström (1982), and Taylor (1982).

view" of the IF-system, and suggest that under certain quite plausible assumptions releases of investment funds may in fact have little impact on a firm's marginal incentive to invest.[1]

The core of this "new view" argument is that each firm faces an upper limit on the use of the investment funds during a release period. This limit is set by the amount of money the firm has "allocated" to its own investment fund in past years, but not previously withdrawn for investments. When this limit is reached additional investment cannot be "financed" through the IF system and the firm, therefore, has to resort to the use of regular depreciation allowances.

The first purpose of this paper is to make the intuitive reasoning of Bergström and Södersten more precise and transparent by developing their argument within an explicit optimizing framework.

Allocations to investment funds take the form of deductions against taxable profits and the tax code restricts the annual allocation to a maximum of 50 per cent of taxable profits. A crucial (implicit) assumption of earlier studies is that the "representative firm" does allocate this maximum proportion of profits to its investment fund each year. Although such behavior would minimize tax payments, empirical evidence suggests that many Swedish firms

---

[1] This "new view" of the IF-system was first developed by Södersten-Lindberg (1983).

in fact do not pursue a policy of maximum IF-allo-
cations.

The second main purpose of this paper, then, is to
analyze the effects of the IF-system when the firm
is constrained in its fund allocations, below the
maximum amounts allowed by the tax law. The alloca-
tion constraint modeled here assumes that after tax
profits reported on the books must not be reduced
below the annual dividend paid by the firm.

The main conclusion of the paper is that the con-
ventional (and official) view of the IF-system
requires some rather special assumptions. During
periods when the funds are released, the "represen-
tative" firm must be able to finance all of the
current investment from its IF and it must also
expect that it will not exhaust its own fund at any
time in the future. Only then will IF-releases be
approximately equivalent to the use of free depre-
ciation for marginal investments. This general
conclusion does not critically depend on whether
the firm makes maximum allocations to its IF or
not.

When these strong assumptions are not fulfilled the
incentive effect of a fund release is much reduced.
The precise impact in this case will depend on
whether or not the firm is able to allocate as much
money to its IF as permitted by the tax rules. If
maximum allocations are made, the profitability of
the marginal investment will depend on the regular
rules of tax depreciation, rather than on the IF-
system. If instead the firm is constrained in its

fund allocations below the legal maximum, an additional investment project will not affect the total tax payments of the firm. The profitability of the marginal investment will therefore be completely independent of the parameters of the tax system.

2   The General Model

The effects of the investment funds system on the incentive to invest may conveniently be analyzed in terms of its impact on the cost of capital. We consider a model in which there is no uncertainty and in which the firm's planning is done under perfect foresight. Its objective is therefore to maximize the present discounted value of future cash flows. We ignore shareholder taxes, because they have little impact on the problems considered here.

The corporate tax system may be characterized in terms of five parameters, γ, τ_s, h, f and b. τ_s is the statutory tax rate and γ is the declining balance rate of fiscal depreciation. A fraction h of the inputed interest on the replacement value of the capital stock may be deducted against taxable profits. Up to f percent of profits net of fiscal depreciation is exempt from tax, provided that the firm "allocates" an equivalent amount to an investment fund (appearing as an entry on the balance sheet). To obtain this tax reduction, however, the firm must deposit a fraction b of the fund allocation interest free at the Central Bank (while the

remainder, 1-b times the allocation, may be used
for any purpose).

When the investment funds are released, firms are
allowed to withdraw from the Central Bank deposits
corresponding to the fraction b of the cost of
investments considered to be "financed" by the fund
release. As an offset to this, however, firms lose
the possibility to deduct fiscal depreciation,
since investments "financed" through the IF-system
are considered to be fully written off for tax
purposes.

Let the value of the firm be

$$V = \int_0^\infty De^{-rt}dt \tag{1}$$

where D denotes cash flow and r is the firm's
(constant) nominal after tax discount rate. To
simplify notation, time indices are omitted here
and in the following. The firm's objective is to
maximize its value, subject to several constraints.
The first are the equations describing the evolu-
tion of the firm's capital stock and accounting
capital stock, respectively.

$$\dot{K} = I - \delta K \tag{2}$$

$$\dot{C} = P_K I - \gamma C - R \tag{3}$$

where $P_K I$ is gross investment, and δ is the rate of
economic depreciation. Regular fiscal depreciation,
which is allowed at the declining balance rate γ,
equals γC. The accounting capital stock is reduced

both by fiscal depreciation and by the current "release" of investment funds, R.

The firm's cash flow identity is:

$$D = PF(K,L) - wL - \tau_s(PF-wL - rhP_KK - \gamma C - B) - P_KI - bB + bR \qquad (4)$$

The tax bill is the tax rate τ_s times "operating profits", PF - wL, less imputed interest on the capital stock, fiscal depreciation and the "allocation" to the investment fund, B. In connection with the IF-allocation, the firm is required to deposit bB with the Central Bank. Similarly, it receives bR from the Central Bank, when the amount R is "released" from its investment fund.

There are two constraints on the amount of money the firm may allocate to its IF: first, and as already stated, we assume that the tax code limits the annual allocation to f percent of profits, net of the deduction for imputed interest and fiscal depreciation:

$$B \leq f \cdot [PF-wL-rhP_KK-\gamma C] \qquad (5)$$

The second constraint takes care of the legal requirement in Sweden that dividends must be paid out of current or accumulated book profits. Since IF-allocations reduce not only after tax accounting profits, but also book profits (because of the close connection in Sweden between tax accounting and book profits), this provision may effectively limit the size of the firm's IF-allocation.

To model this constraint we interpret D as dividends and to simplify, we assume that each year's dividend must be paid out of the same year's after tax book profits. We therefore require that:

$$B \leq PF - wL - rhP_K K - \gamma C - \frac{D}{1-\tau_s} \qquad (6)$$

where $D/1-\tau_s$ is the amount of pre-tax book profits required to cover the current dividend.

We require, furthermore, the investment fund's balance to be non-negative at all times

$$IF \geq 0 \qquad (7)$$

The change in the fund's balance is by definition

$$I\dot{F} = B-R \qquad (8)$$

There are, finally two constraints on withdrawals from the fund, stating that the firm cannot at any time withdraw funds in excess of its current investment, and that the amount withdrawn cannot be negative. Formally this means that

$$R \leq P_K I \qquad (9)$$

$$R \geq O \qquad (10)$$

The firm chooses I, L and B to maximize V (equation (1)) subject to equations (2) to (10). The firm's problem may be rewritten as

$$\max V = \int_0^\infty e^{-rt}[D+\lambda_1(\dot{K}-I+\delta K)+\lambda_2(D-PF+wL+\tau_s[PF-$$

$$wL-rhP_KK-\gamma C-B] + P_KI + bB - bR) +$$

$$\lambda_3(\dot{C}-P_KI+\gamma C+R) + \eta_1(B-f\cdot[PF-wL - rhP_KK-\gamma C] +$$

$$\eta_2(B-[PF-wL-\gamma C-rhP_KK - \frac{D}{1-\tau_s}])$$

$$+ \beta_1 IF + \beta_2(I\dot{F}-B+R) + \beta_3(R-P_KI)+\beta_4R]dt \quad (11)$$

where λ_1, λ_2, λ_3, η_1, η_2, β_1, β_2, β_3 and β_4 are the Lagrange multipliers associated with the constraints.

The first order necessary conditions for an optimal program are:

$$D: \quad 1 + \lambda_2 + \frac{\eta_2}{1-\tau_s} = 0 \quad (12)$$

$$I: \quad -\lambda_1 + P_K(\lambda_2 - \lambda_3 - \beta_3) = 0 \quad (13)$$

$$K: \quad \lambda_1(\delta+r) - PF_K'(\lambda_2(1-\tau_s)+\eta_1f+\eta_2) +$$
$$+ rhP_K(-\lambda_2\tau_s+\eta_1f+\eta_2) - \dot{\lambda}_1 = 0 \quad (14)$$

$$B: \quad -\lambda_2(\tau_s-b) + \eta_1 + \eta_2 - \beta_2 = 0 \quad (15)$$

$$\eta_1(B-f\cdot(PF-wL-rhP_KK-\gamma C)) = 0$$

$$\eta_2(B-(PF-wL-rhP_KK-\gamma C - \frac{D}{1-\tau_s})) = 0$$

$$C: \quad \lambda_3(\gamma+r) + \gamma(-\lambda_2\tau_s+\eta_1f+\eta_2) - \dot{\lambda}_3 = 0. \quad (16)$$

$$R: \quad - \lambda_2b + \lambda_3 + \beta_2 + \beta_3 + \beta_4 = 0 \quad (17)$$

$$\beta_3 (R-P_KI) = 0$$

$$\beta_4R = 0$$

IF: $\beta_1 + r\beta_2 - \dot{\beta}_2 = 0$ (18)

$\beta_1 IF = 0$

By interpreting these conditions we can determine the effects of the IF-system on the cost of capital.

3   The IF-system and the cost of capital

a)   A standard of comparison

In order to obtain a clear standard of comparison, we will start by deriving the cost of capital in the absence of the IF-system. We therefore set all parameters of equations (12)-(18) associated with the IF-system (B, R, f, the η:s and β:s) equal to zero, and solve for PF'_K/P_K. This is the gross rate of return before tax on real investment on the optimal path, i.e. the (gross) cost of capital:

$$\frac{PF'_K}{P_K} = \frac{\frac{-\lambda_1}{P_K}}{1-\tau_s} (\delta + r - \frac{\dot{\lambda}_1}{\lambda_1}) - \frac{rh\tau_s}{1-\tau_s}$$ (19)

where

$$\frac{-\lambda_1}{P_K} = 1 + \lambda_3$$

and

$$-\lambda_3 = \int_{s=t}^{\infty} \gamma\tau_s e^{-(\gamma+r)(s-t)} ds$$

$-\lambda_3$ is thus the present discounted value of tax reductions from regular depreciation allowances, taken at the declining balance rate γ. $-\lambda_1/P_K$ is therefore the "net cost of investment", that is, the net cost to the firm of acquiring an asset of unit value.[1] For τ_s and γ constant over time, (19) simplifies to:

$$\frac{PF'_k}{P_K} = \left(\frac{1-\frac{\tau_s\gamma}{\gamma+r}}{1-\tau_s}\right)(\delta+r-\Pi) - \frac{rh\tau_s}{1-\tau_s} \qquad (20)$$

where $\Pi = \dfrac{\dot{P}_K}{P_K}$

Equation (20) differs from the standard expression for capital cost only by the last term, which explicitly captures the effect of interest deductability.[2]

When the rate of fiscal depreciation, γ, is greater than the rate of economic depreciation, δ, depreciation allowances are said to be accelerated. A special and important case of accelerated depreciation is where firms are allowed to deduct investment expenditures for tax purposes. This is often known as free depreciation or expensing. Note then that since tax accounting values are given here in exponential form, the mathematical equivalent of free depreciation is that the rate of fiscal depreciation, γ, is infinitely large. Capital cost with free depreciation is therefore given by

----

[1] This term is used by, for instance, King and Fullerton (1984).

[2] Cf. King and Fullerton (1984), p XXX.

$$\frac{PF'_K}{P_K} = \delta + r - \Pi - \frac{rh\tau_s}{1-\tau_s} \qquad (21)$$

where $\Pi = \dot{P}_K/P_K$.

The important thing to notice from equation (21) is that the profits tax now lowers the cost of capital. This is a well-known result, which is driven by the combination of interest deductibility and free depreciation.[1]

According to the conventional view of the IF-system, fund releases are approximately equivalent to the use of free depreciation. This conventional view is usually explained in the following intuitive way: Because IF-allocations are free of tax, only the share 1-f of profits is taxed at the statutory tax rate τ_s. The fund allocation, which amounts to the fraction f of profits, is instead

----

[1] See for example King (1975) and King and Fullerton (1984). K&F show that where the tax system allows both full deductibility of interest and free depreciation, the nominal net cost of capital is equal to the interest rate multiplied by unity minus the corporate tax rate. Where interest is not deductible, as is usually the case with respect to the opportunity cost of equity funds, free depreciation makes capital cost invariant with respect to changes in the tax rate, i.e. equal to the interest rate. These results also come out of the present model.

No interest deductability means that h=0. The net (real) cost of capital is then $PF'_K/P_K - \delta = r - \Pi$. Since free depreciation means that a fraction τ_s of the investment is financed by deferred tax which may be interpreted as an interest free loan to the firm (cf. Södersten, 1982), interest deductability cannot reasonably be granted on more than the proportion $1-\tau_s$ of the capital stock. Putting $h=1-\tau_s$ in equation (21) then gives the well known result that $PF'_K/P_K - \delta = r(1-\tau_s) - \Pi$.

"taxed" at the rate b, which is the proportion which must be paid to the Central Bank. The "effective" tax rate, which we denote by T*, is therefore a weighted average of the statutory tax rate τ_s and the "deposit rate" b:

$$T^* = \tau_s(1-f) + bf$$

When the funds are released by the government, firms withdraw from the Central Bank the amount b, per crown of investment considered to be "financed" through the system. The "net cost of investment" is therefore 1-b, and cost of capital will then be

$$\frac{PF'_K}{P_K} = (\frac{1-b}{1-T^*})(\delta+r-\Pi) - \frac{rhT^*}{1-T^*} \tag{22}$$

Equation (22) differs from equation (21), which states the cost of capital in the case of free depreciation, only to the extent that the statutory tax rate τ_s is different from the deposit rate b.

b)   General Results

We are now ready to analyze the effects of the IF-system. The general expression for the cost of capital with the IF-system is obtained from equation (14) as

$$\frac{PF'_K}{P_K} = \frac{-\frac{\lambda_1}{P_K}(\delta + r - \frac{\dot{\lambda}_1}{\lambda_1})}{-\lambda_2 - T^*} - \frac{r h T^*}{-\lambda_2 - T^*} \tag{23}$$

where

$$T^* = -\lambda_2 \tau_s + \eta_1 f + \eta_2,$$

$$-\lambda_2 = 1 + \frac{\eta_2}{1 - \tau_s} \qquad \text{(from equation 12)} \qquad \text{(23a)}$$

and

$$-\frac{\lambda_1}{P_K} = -\lambda_2 + \lambda_3 + \beta_3 \qquad \text{(from equation 13).}$$

As will be evident below, T^* is the firm's "effective" tax rate, the value of which will depend on what particular assumptions we make about the workings of the fund system. The multipliers $-\eta_1$ and $-\eta_2$ express the marginal benefit to the firm from allocating money to its IF. When maximum allocations are made, $-\eta_2 = 0$ and $-\eta_1 > 0$, whereas $-\eta_2 > 0$ and $-\eta_1 = 0$ when "the dividend constraint" on fund allocations is binding. λ_2 has an economically interesting interpretation as the marginal value of dividends, showing the change in the firm's market value resulting from an extra crown of dividends. Conversely, $-\lambda_2$ is the marginal valuation of retained earnings, or marginal Tobin's q. $-\lambda_2$ takes the value of unity when the firm allocates as much of its profits to its IF as allowed by the tax code ($\eta_2 = 0$), and less than unity when maximum allocations are not made ($\eta_2 < 0$). We shall return to this interpretation of $-\lambda_2$ in Section 3d below.

As before $-\lambda_1/P_k$ is the net cost of investment. In this general case it depends also on λ_2 and on β_3, which is the net marginal gain to the firm from an IF-release. From equation (17) it is immediately clear that $\beta_3 = 0$ when $R < P_K I$, i.e. when the amount of money released from the fund is less than

current investment. The net cost of investment
therefore depends not only on whether or not the
system is in a release stage but also on whether
the amount of money actually released from the
firm's IF during a release period is sufficient to
"finance" its current investment. If $R < P_K I$ the
marginal investment must be written off according
to the rules of regular fiscal depreciation, rather
than through the IF-system.

It should be clear from these remarks that the
effects of the IF-system on the cost of capital in
general cannot be determined without precise as-
sumptions on which regime the firm is in, at pres-
ent and in the future. The purpose of the following
sections is to distinguish between six regimes,
each having a different implication for the cost of
capital. The regimes are characterized by whether
or not the firm is constrained in its IF-alloca-
tions, by whether or not the system is in a release
stage and by whether the amount released from the
fund during a release period is sufficient to
"finance" its current investments. It should be
pointed out, that the different regimes are defined
for the purpose of clarity and economic interpreta-
tion and that the firm, obviously, may switch be-
tween the different regimes over time. The model
used here is indeed sufficiently general to allow
for such switches.

c)   The Case of Maximum IF-Allocations

We start the analysis by assuming that the firm now
and in the future allocates as much of its pre-tax

profits to its IF as allowed by the tax code. This means that $\eta_2(s) = 0$ for all s and (by equation (23a)) that $- \lambda_2(t) = 1$. Irrespective of whether the funds are released or not, the expression for the cost of capital (equation 23 above) then simplifies to

$$\frac{PF'_K}{P_K} = \frac{\frac{-\lambda_1}{P_K}(\delta + r - \frac{\dot{\lambda}_1}{\lambda_1})}{1 - T^*} - \frac{rhT^*}{1 - T^*} \qquad (24)$$

where

$$T^* = \tau_s(1 - f) + bf + \beta_2 f \qquad (25)$$

which is a weighted average of the statutory tax rate and the Central Bank deposit rate <u>plus</u> the multiplier β_2. This multiplier will be in the focus of the following analysis and from equation (11) we find that (written with a negative sign) it is the marginal gain from increasing the size of the investment fund. The investment fund allocation (which is f per crown of pre-tax profits) is therefore "taxed" at the rate $b + \beta_2$, which is the Central bank deposit rate <u>less</u> the gain from increasing the firm's IF. From equation (18) we have that

$$- \beta_2(t) \int_{s=t}^{\infty} \beta_1(s)e^{-r(s-t)}ds \qquad (26)$$

where $\beta_1(s)$ is the shadow price of the stock of funds at time s. The value of $\beta_2(t)$ therefore depends on the entire future development of the fund. $\beta_1(s)$ is zero when the fund's balance is positive, and $\beta_2(t)$ is therefore zero only in the special and

extreme case where the firm expects that in the future it will never exhaust its fund. Further increases in the stock of funds are then of no value to the firm. It is also clear from equation (26) that the sooner and the more often the firm expects to exhaust its fund, the higher is $-\beta_2(t)$. The maximum value of $-\beta_2(t)$ cannot be determined without further assumptions, however, but we shall return to this question below.

The basic results of the analysis for the first three regimes are summarizewd in Tables 1 and 2. Table 1 gives the net cost of investment, $-\lambda_1/P_K$, and Table 2 shows, for special cases, the resulting expressions for the cost of capital.

Table 1   The net cost of investment $(-\lambda_1/P_K)$ in the case of maximum IF-allocations
Regimes 1-3

No release of funds	Fund release	
	$R = P_K I$	$R < P_K I$
$1+\lambda_3$	$1-b-\beta_2$	$1+\lambda_3$
(1)	(2)	(3)

Note: ( ) states regime number. $-\lambda_3$ is the present discounted value of tax savings from regular tax depreciation (see equation 28), and $-\beta_2$ is the marginal gain from increasing the size of the IF. The general expression for the cost of capital in the case of maximum IF-allocations is given by (24) above.

Table 2 The cost of capital for regimes 1-3 in some special cases

No release of funds $(-\beta_2 = 0)$	Fund release	
	$R = P_K I$ $(-\beta_2 = 0)$	$R < P_K I$ $(-\beta_2\text{-max})$
$(\dfrac{1-T^*\frac{\gamma}{\gamma+r}}{1-T^*})(\delta+r-\Pi) - \dfrac{rhT^*}{1-T^*}$	$(\dfrac{1-b}{1-T^*})(\delta+r-\Pi) - \dfrac{rhT^*}{1-T^*}$	$(\dfrac{1-T^*\frac{\gamma}{\gamma+r}}{1-T^*})(\delta+r-\Pi) - \dfrac{rhT^*}{1-T^*}$
(1)	(2)	(3)

Note: $-\beta_2$-max is given by equation (31) for regime 3.
$T^* = \tau_s(1-f) + fb$ for __regimes 1__ and 2, and $T^* = \tau(1-f) + fT^*\dfrac{\gamma}{\gamma+r}$ for __regime__ 3. The statutory tax rate τ_s and the rate of fiscal depreciation γ are assumed to be unchanged over time. We then get that $\Pi = \dot\lambda_1/\lambda_1 = \dot P_K/P_K$, which is the rate of change for investment goods prices.

Let _regime 1_ represent the case where the funds are not released for financing investments. $R = 0$ means that $\beta_3 = 0$. The net cost of investment is therefore

$$- \frac{\lambda_1}{P_k} = 1 + \lambda_3 \qquad (27)$$

where as before $- \lambda_3$ is the present discounted value of tax reductions from regular depreciation allowances:

$$- \lambda_3 = \int_{s=t}^{\infty} T^* \gamma \ e^{-(\gamma+r)(s-t)} ds \qquad (28)$$

The effective tax rate T^* is as defined above by equation (25). For _regime 1_, therefore, the effect of the IF-system is to turn the corporate tax rate into a weighted average of the statutory tax rate τ_s and the sum of the deposit rate b and β_2, which is (the negative of) the marginal gain from adding to the IF.

For regimes 2 and 3 we assume that IF-system is currently in a release stage, i.e., $R>0$. _Regime 2_ is where the amount of release is sufficient to "finance" current investment ($R=P_K I$). This means that $-\beta_3(t)>0$ and from equations (17) and (13) we get the net cost of investment

$$- \frac{\lambda_1}{P_K} = 1-b-\beta_2 \qquad (29)$$

In this case, therefore, both the net cost of investment and the effective tax rate T* depend on β_2. The conventional view of the effects of IF-releases explained above (see equation (22)) turns out to represent an extreme case of this regime, namely where $\beta_2 = 0$, that is, it implicitly assumes that the firm will never exhaust its IF.

Regime 3 is the case where $R < P_K I$. This means that $\beta_3 = 0$, making

$$- \frac{\lambda_1}{P_K} = 1 + \lambda_3 \qquad (30)$$

where λ_3 is defined as in equation (28). The difference between the cost of capital under regime 1, where the funds are not released, and regime 3, where the funds are released but insufficient to "finance" all investment is therefore determined by the values of $\beta_2(t)$. Somewhat loosely we may conclude that if the firm proceeds over time from regime 1 to regime 3, $-\beta_2(t)$ will be higher under regime 3 and the cost of capital therefore lower -though the difference need not be great. The reason for this may be seen from equation (26): As long as the firm is not allowed to use its IF, but keeps building it up, β_1 is zero.

It is also interesting to note that while the minimum value of $-\beta_2$ is zero under regime 1, it must exceed zero for regime 3, since the assumption that $R < P_K I$ implies that the firm is currently exhausting its fund. The maximum value of $-\beta_2$, on the other hand, is greater for regime 3: It occurs in the

extreme case where the firm expects a permanent release of funds and when it always will exhaust its fund. After a few manipulations, equations (16) and (17) give this maximum value as

$$- \beta_2 = b - \frac{\tau_s \gamma (1-f)}{\gamma (1-f) + r} \tag{31}$$

The effective tax rate T*, defined by equation (25), then turns into

$$T^* = \tau_s (1-f) + f \frac{\tau_s \gamma (1-f)}{\gamma (1-f) + r}$$

$$= \tau_s (1-f) + fT^* \frac{\gamma}{\gamma + r} \tag{32}$$

This expression for the effective tax rate has a clear economic interpretation: A fraction 1-f of profits will be taxed at the statutory tax rate τ_s, while the fraction f is allocated to the IF. By the assumption of a permanent release of funds, this extra fund allocation can immediately be used for (intramarginal) investment. The Central Bank deposit rate b is therefore of no importance. There is, however, an implicit cost to the firm of the allocation, and this cost equals the increased tax payments due to the loss of regular depreciation allowances on the subsequent assets, financed by the allocation, i.e., $T^* \gamma / (\gamma + r)$. For this special case of regime 3 where the firm always exhausts its fund and expects the period of fund release to be extended indefinitely, the effect of the IF-system is therefore to turn the tax rate into a weighted average of the statutory tax rate and the implicit cost of fund allocation. This is the "new view" interpretation of the IF-system, developed in Bergström-Södersten (1984).

d   The Case of Constrained IF-Allocation

We now proceed to the case where the firm now and
in future allocates less money to its IF than al-
lowed by the rules. We have allowed for this possi-
bility by introducing a dividend constraint (equa-
tion (6) above) which is assumed to be binding in
the following. This means that $\eta_1(s)=0$ for all s,
and from equation (12), (15) and (23a) we get that

$$T^* = (\frac{1-\tau_s}{1-b})(b+\frac{\beta_2}{1-\tau_s}) \tag{33}$$

Since in this case $\eta_2 < 0$, $-\lambda_2$, which is the stock
market's marginal valuation of retained earnings
(or new investment), is now less than unity. The
reason for this is that profits now are "trapped"
within the firm in the sense that any increase in
dividends will tighten the dividend constraint on
IF-allocations and force the firm to pay more in
corporate tax. Put differently, shareholders would
be willing to accept less than a crown's worth of
capital gains, for the marginal crown of retained
earnings. We note here that this is the same under-
valuation result as that obtained from the so
called "new view" of equity finance. The point of
this new view is that because personal taxes on
dividends cannot be avoided and because capital
gains receive a preferential tax treatment, the
stock market will value new investments financed by
retained earnings at less than their reproduction
costs.[1]

----
[1]   See Södersten-Bergström (1981), Bradford (1981)
and Auerbach (1979).

Equations (12) and (15) gives that

$$-\lambda_2 = (\frac{1-\tau_s}{1-b})(1+\frac{\beta_2}{1-\tau_s}) \tag{34}$$

By equations (33) and (34), $\lambda_2 - T^* = 1 - \tau_s$. The general expression for the cost of capital (equation (23) above) then simplifies to

$$\frac{PF'_K}{P_K} = \frac{\frac{-\lambda_1}{P_K}(\delta + r - \frac{\dot{\lambda}_1}{\lambda_1})}{1 - \tau_s} - \frac{rhT^*}{1-\tau_s} \tag{35}$$

where T^* is the effective tax rate as given in (33) and $-\lambda_1/P_K$ is the net cost of investment.

We proceed as before by distinguishing between three regimes, characterized by whether or not the IF-system is in a release stage and by whether or not the firm during a release period is able to finance its current investment through the IF. Table 3 summarizes the implications for the net cost of investment in each of these three regimes (regimes number 4-6) and Table 4 gives the resulting expressions for the cost of capital for some special cases.

Table 3   **The net cost of investment $(-\lambda_1/P_K)$ in the case of constrained IF-allocations. Regimes 4-6**

No release of funds	Fund release	
	$R = p_K I$	$R < P_K I$
$(\frac{1-\tau_s}{1-b})(1+\frac{\beta_2}{1-\tau_s})+\lambda_3$	$1-\tau_s$	$1-\tau_s$
(4)	(5)	(6)

Note: ( ) states regime number. $-\lambda_3$ is the present discounted value of tax savings from regular tax depreciation (see equation (28)), and $-\beta_2$ is the marginal gain from increasing the size of the IF. The general expression for the cost of capital in the case of maximum IF-allocations is given by (35) above.

**Table 4 The net cost of capital for regimes 4-6 in some
special cases**

No release of funds $(-\beta_2 = 0)$	Fund release	
	$R = P_K I$ $(-\beta_2 = 0)$	$R < P_K I$ $(-\beta_2 = b(1-\tau_s))$
$(\dfrac{1 - \dfrac{b\gamma}{\gamma + r}}{1-b})(\delta + r - \Pi) - \dfrac{bhr}{1-b}$	$\delta + r - \Pi - \dfrac{bhr}{1-b}$	$\delta + r - \Pi$
(4)	(5)	(6)

Note: (   ) states number of regime. For regimes (4) and (5)
$-\beta_2 = 0$, which is the minimum value, while for regime 6,
$-\beta_2 = b(1-\tau_s)$ (see equation (37)).

Regime 4 is where the fund system is not in a re-
lease stage. This means that $\beta_3 = 0$ and by equations
(13) and (34)

$$\frac{-\lambda_1}{P_K} = (\frac{1 - \tau_s}{1 - b})(1 + \frac{\beta_2}{1 - \tau_s}) + \lambda_3$$

where as before $-\lambda_3$ is the present discounted value
of tax savings from regular depreciation allov-
ances. The net cost of investment and the cost of
capital will thus depend on the current and future
values of β_2 which in turn depend on the expected
future development of the firm's IF. For the spe-
cial case, where $\beta_2 = 0$, i.e., where the firm expects
that it will never exhaust its fund, the effect of
the IF-system(see Table 4, regime 4) is just to
replace the statutory tax rate τ_s in the standard
expression for capital cost without the IF-system
(see equation (20) above) by the Central Bank de-
posit rate b. A comparison between regimes 1 and 4
for the special case of $\beta_2 = 0$, makes it clear, fur-
thermore that the constraint on fund allocations
modelled here is equivalent to allowing the firm of
regime 1 to allocate all of its profits from its
marginal investment (i.e. f=1) to its IF.

For regime 5 we assume again that the IF system is
currently in a release stage, and that $R = P_K I$.
This means that $\beta_4 = 0$. The net cost of investment
then turns out to be (from equations (13), (17) and
(34)):

$$- \frac{\lambda_1}{P_K} = 1 - \tau_s \tag{36}$$

From equations (35) and (36) it is clear then that capital cost is affected by the tax system only to the extent that the tax code allows for deduction of interest. The higher the firm values additions to its IF (i.e. the lower is β_2; note that $\beta_2 < 0$) - which occurs the sooner and the more often it expects to exhaust its IF in the future - the lower is T* and therefore the value of interest deductions. The highest value of interest deductions is when β_2 is zero. This is the "excess funds" case where the firm expects that it will never exhaust its IF. In this special case the cost of capital therefore differs from that of free depreciation only to the extent that b differs from τ_s.

Regime 6 is where $R < P_K I$. This means that $\beta_3 = 0$ and the net cost of investment is again $1 - \tau_s$. In this case we are able to solve for β_2. By equations (17) and (34)

$$- \beta_2 = b(1 - \tau_s) + \lambda_3(1-b) \tag{37}$$

making T* = $-\lambda_3$. Equation (16) then simplifies to

$$\lambda_3 r - \dot{\lambda}_3 = 0 \tag{38}$$

One solution to this differential equation - and the only one with economic significance - is $\lambda_3 = 0$. The implication of this is that T* = 0 and $-\beta_2 = b(1-\tau_s)$. Interest deductability is of no value and the cost of capital then becomes

$$\frac{PF_K'}{P_K} = \delta + r - \Pi \qquad\qquad (39)$$

Combining the assumptions that the fund release is not sufficient to finance (the marginal) investment and that fund allocations are constrained below maximum, therefore makes capital cost completely independent of the parameters of the tax system.

To see the intuition behind this result, note that $-\lambda_2$, which is marginal Tobin's q, now is $1 - \tau_s$. This discount in the valuation of the stock market is just sufficient to offset the effects of the tax making the cost of capital completely tax invariant.

e   Effects of New Rules

So far, we have implicitly assumed that the required deposit with the Central Bank (b) is lower than the statutory tax rate (τ_s). Because of this, IF allocations provide an attractive alternative to paying profits tax even if the funds are never used again for investment.[1]

By new rules in force since 1985, however, b is higher than τ_s. Firms that allocate profits to their investment funds therefore have to pay a "fee" (equal to the difference $b-\tau_s$), in exchange

---

[1] b was 0.46 during 1963-79 and 0.5 1980-84, while τ_s ranged between 0.52 and 0.58. Since 1985, however, b is 0.75 and τ_s 0.52. This increase might be seen as an attempt by the government to force firms to pay fees to the new wage-earners funds, rather than avoiding the fees by large IF-allocations.

for expected future benefits when the funds are released.

The multipliers $-\eta_1$ and $-\eta_2$ may be interpreted as the marginal benefits from allocating profits to the IF. Since $-\eta_1 \geqq 0$ and $-\eta_2 \geqq 0$, positive allocations require that (by equation 15) $-\beta_2 \geqq b - \tau_s$. By the new rules (b > τ_s) this condition requires that $-\beta_2$, which is the marginal gain from increasing the firm's IF, is positive and outweighs the "allocation fee" $b - \tau_s$. The conventional and official view of the IF-system, which implicitly assumes that $-\beta_2 = 0$, is therefore not compatible with the condition required for positive fund allocations under the new rules.

4   Conclusions

The general conclusion which emerges from this paper is that the effects of the investment funds system critically depend on which regime the firm is in when the funds are released by the government and which regime it expects to be in in the future. It has to look to the future because the profitability of increasing the capital stock today depends on the effective tax rates that will prevail in the future and these depend, _inter alia_, on the future development of its own IF. A further illustration to the results is given in Table 5, which gives some numerical examples based on the equations of Tables 2 and 4. The difference between regime 2 in the special case where $\beta_2 = 0$ - which represents the conventional view of the system -and the "$-\beta_2$-max" case of regime 3 is particularly striking.

Table 5 **Numerical illustration of capital cost effects of the investment funds system in some special cases**

Allocation to IF	No release of funds $(-\beta_2=0)$	Fund release	
		$R=P_K I$ $(-\beta_2=0)$	$R<P_K I$ $(-\beta_2 max)$
Maximum	6.6	1.7	6.0
	(1)	(2)	(3)
Below maximum	6.5	1.5	5.0
	(4)	(5)	(6)

The following assumptions are used: $\gamma = 0.2$, $\delta = 0.1$, $r = 0.10$, $\Pi = 0.05$, $\tau_s = 0.52$, $b = 0.5$, $h = 0.35$. The cost of capital without the IF-system is then 6.6 %. Free depreciation reduces capital cost to 1.2 %, whereas without the corporate tax capital cost is 5.0 %. See p. 12 for an explanation of this.

Note that the numbers given here are for the net cost of capital, defined as

$$\frac{PF'_K}{P_K} - \delta.$$

"$-\beta_2 max$" is given by equation (31) for regime 3 and by equation (37) for regime 6.

The appropriate policy conclusions to be drawn from
these results hinges on which of the regimes we
have studied that represents the best characteriza-
tion of the position of Swedish firms. This is, of
course, an empirical question which must be settled
through careful study of individual firm data. In
this context it is interesting to note the marked
change in tax policy that took place in Sweden in
the mid 70s. From its start in 1955 to the mid 70s
the IF-system was used primarily as a counter-
cyclical instrument with releases in recessions.
The crisis of the Swedish economy which emerged in
the mid 70s, however, led the government to embark
upon a new IF-policy. This new policy means re-
peated renewals of IF-releases, which i practice,
enabled firms during a 10-year-period to use their
investment funds continuously. During this period
of "permanent" releases, less than an average of 20
per cent of the investments of the manufacturing
industry were actually "financed" through the IF-
system. This observation makes it rather unlikely
that the "representative" firm then was able to
finance its marginal investments through the IF-
system and that it expected never to exhaust its
investment fund. As explained, these are the criti-
cal implicit assumptions behind the conventional
- and official - view of the IF-system. The IF-
releases may in practice have raised the return on
intramarginal investments more than it improved
investment incentives.

Finally, a few reservations are in order. The pol-
icy conclusions that may be drawn from the results
of this paper, are, of course, no more reliable
than is the underlying model of firm behavior. In

particular, we have focused interest on the cost of
capital effects. There might, for example, still
exist a "liquidity effect" of IF-releases. Consid-
ering the poor performance of the Swedish stock
market during the second half of the 70s making new
share issues expensive and the remaining restric-
tions on credit availability, such effects may have
been important determinants of investment demand.
