Gender Quotas in the Board Room and Firm Performance: Evidence from a Credible Threat in Sweden

Björn Tyrefors and Joakim Jansson

Gender Quotas in the Board Room and Firm Performance: Evidence from a Credible Threat in Sweden

By BJÖRN TYREFORS HINNERICH AND JOAKIM JANSSON*

THIS VERSION: 2017-04-05

Board room quotas have recently received an increasing amount of attention. This paper provides novel evidence on firm performance from an exogenous change in female board participation in Sweden. We use the credible threat, aimed at listed firms, of a quota law enacted by the Swedish deputy prime minister as an exogenous variation. The threat caused a substantial and rapid increase in the share of female board members in firms listed on the Stockholm stock exchange. This increase was accompanied by an increase in different measures of firm performance in the same years, which were related to higher sales and lower labor costs.

I. Introduction

Policymakers in Europe have recently begun to focus on the relative underrepresentation of women on corporate boards, and numerous countries are considering the implementation of gender quotas. The first quota law, adopted in Norway in December 2005, required public limited liability companies (ASA) to increase female representation on their boards of directors to 40 percent within two years. The law increased female representation by approximately 20 percentage points for the typical firm (Matsa and Miller 2013). Other countries, including Spain, Belgium, France, Germany, Iceland, Italy and the Netherlands, have subsequently implemented quotas (Eckbo, Nygaard and Thorburn 2016). In Sweden, the policy debate has been intense as well. In 2002, Swedish Deputy Prime Minister Margareta Winberg, supported by Prime Minister Göran Persson, threatened to impose a mandatory law if considerable improvements in board room representation were not achieved in the listed companies within two years. Specifically, the listed companies were asked to increase their share of female directors to 25 %, an increase of approximately 20 percentage points. From a standard economics perspective, it is reasonable to conjecture that a quota law or a credible threat of a law should (weakly) reduce profits. However, if there is excess supply of managerial and/or firms engage in taste-based discrimination, then a reduction of profits might not occur (Ferreira 2015).¹

In addition, more female directors will only improve firm performance if female directors differ from male directors. As discussed in Adams (2016), diversity could be either temporary or more of a permanent type. Differences such that female directors are likely to be younger as (see e.g. Adams & Ferreira, 2009 and

¹ Other proposed arguments for a non-negative effect include the notion that a board is simply “window dressing”, thereby having no effect on business.

Adams & Funk, 2012) or being an outsider of the “old boys club” is, likely to change over time. More stable gender differences related to decision making are differences in preferences and attitudes such as differences in risk attitudes, attitudes toward competition and negotiations.² For example, it has been suggested that the Lehman brothers’ crisis never would have occurred if it would have been Lehman Sisters (Adams and Raganathan, 2014). However, this argument misses out on the selection into boards as pointed out and documented by Adams and Funk (2012). They do not find support that the female directors in Sweden would be representative for the population of females. In fact they find that the female directors are less risk adverse, invalidating the Lehman’s sisters “hypothesis” with respect to risk aversion differences. The documented selection of non-representative types also highlights the fact that without exogenous variation in female representation, it is hard to make causal statements with respect to gender. The Norwegian law of quotas in 2005 has been used as such an exogenous shock (Ahern and Dittmar, 2012 and Matsa and Miller, 2013).³

Ahern and Dittmar (2012) use the pre-reform share of women on the board of listed firms and the fact that early adopters are not affected by the law to the same extent. Using this strategy, they find a large negative effect on firms’ Tobin’s Q ratio. However, as discussed by Ferreira (2015), early adopters are unlikely to be similar in trends to their counterpart. When we replicate their first stage in our setting, the parallel trend assumption is violated due to mean reversion. This finding is illustrated in Figure A1 in the Appendix.

Matsa and Miller (2013) exploit a similar design to ours, in which non-listed limited liability firms act as the control group to the listed firms. Again, the effect

² See e.g. the survey of the literature and empirical evidence in Bertrand (2011).

³ The Norwegian reform was implemented sequentially in practice. The first discussions began in 1999, and the first proposal was released in 2001 by the then center-left government. In 2002 the newly elected center-right government made statements both in support of and in defiance against a quota law, which in the end resulted in a law being passed in late 2005. The law in turn gave the affected companies two years to comply.

found in Matsa and Miller (2013) on firm performance is negative.⁴ Conversely, Nygaard (2011) finds a positive effect of quotas on firm performance when evaluating the Norwegian reform. However, the robustness of the results from these papers has been questioned (Ferreira 2015; Eckbo, Nygaard and Thorburn 2016). When critically assessing the empirical design used in previous papers, Eckbo, Nygaard and Thorburn (2016) find a zero effect of the quota reform. One major point made in Eckbo, Nygaard and Thorburn (2016) is that firms could anticipate the law after the political debate changed in February 2002. Anticipatory effects are a direct threat to validity in a difference-in-difference setting (Angrist and Pischke 2009). Thus, a credible difference-in-difference strategy uses the first date when the law was anticipated as treatment date.

Given the large degree of disagreement regarding the effects of the Norwegian reform and the debate regarding the suitability of using the Norwegian setting for causal interpretation, we propose another testing ground to provide evidence of the effects of gender quotas. We use a credible threat by the Swedish deputy prime minister as the exogenous variation. We try addressing the methodological concerns discussed in Ferreira (2015) and Eckbo, Nygaard and Thorburn (2016).

The threat caused a substantial and rapid increase in the female board share in firms listed on the Stockholm stock exchange; the short term effect size was approximately 5-10 percentage points or an approximately 100-200 percent increase. Interestingly, this increase was accompanied by an increase in the measures of firm performance in the exact same years. On average, profits over assets increased by approximately 2-4 percent of assets among listed firms after the threat, relative to the change in profits in unlisted firms in the same time

⁴The authors pick the treatment period as post-2006. As Figure 1 in Bertrand et al. (2014) demonstrates, the increase in the share of females on boards began back in 2002 and continued until 2008. Thus, their first stage does not seem to exhibit parallel trends prior to their treatment period.

period. We can generally reject effect sizes that are smaller than 0.5 percent using a 95 percentage confidence interval. However, increased female representation on boards did not lead to the higher recruitment of females as CEOs, either in the short or the long run. In fact, our results indicate the opposite, suggesting that certain female CEOs were recruited to the boards and not always replaced by female CEOs. Moreover, labor costs decreased and sales increased, although not estimated with high precision. Our results indicate that parallel trends are a reasonable assumption. In addition, our standard errors are robust when collapsing the data to the highest level.

The remainder of the paper is outlined as follows: In section 2, we document the background of the threat. In section 3, we describe the methodology, data, and sampling. In section 4, we provide the results, and in section 5 we conclude.

II. Background

Sweden has a long history of male-dominated board rooms in listed companies. In the 1990s, the female share was steady at just below 5 %. In 2003, the female share began to increase, tripling within 3 years. Anecdotally, the increase has been attributed to threats of a gender quota law made by the minister of gender equality, Margareta Winberg, during the second half of 2002. Winberg, a prominent feminist figure with a long history in the Social Democratic Party and the government, took office in 1998 as a minister of gender equality. In our study, identification is linked to the timing of the threat, and therefore it is crucial to describe the threats carried out over time. Figure 1 shows the number of printed articles in newspapers in Sweden, a major channel used by policy makers to propose new policy ideas. The number of articles is based on a search that

includes the minister's name, quota, women and board.⁵ In 1999, as depicted in Figure 1, Winberg began to discuss, although rarely, the role of board room quotas for women in listed companies. Previously, she had acknowledged that a female quota in the business world could be problematic since competencies might be scarce. In three articles in leading Swedish newspapers in 1999, Winberg stated that she was not averse to a law but hoped instead to see voluntary improvements within 5 years. In the following years, gender quotas in the board rooms were absent from the debate, as depicted in Figure 1.

[Insert Figure 1 Here]

In 2002, the temperature rose. During the year, the number of printed articles mentioning Winberg's name in combination with quotas, women and boards exploded. In July, in the leading business daily *Dagens Industri*, Winberg indicated that she was contemplating a quota law to increase the pressure on listed firms. (*Dagens Industri* 2002-07-17). As a result, the debate became heated. Following Winberg's appointment as deputy prime minister in October, a series of articles intensified the tone and outlined the quota threat in detail. In an article in the *Dagens Industri*, she stated that "the threat is real", noting that if the listed companies were not making significant progress, "there will be a law" (*Dagens Industri* 2002-10-22). In another article in the leading daily paper *Svenska Dagbladet*, Winberg defined significant progress: the share of female directors must increase to 25 % within two years. She noted that she had full support from Prime Minister Göran Persson and that a formal "Investigation Directive" was under way and would be ready by the spring. After that, a formal investigation could proceed. Winberg estimated that the law would be ready in 2004 or 2005.

⁵ Source: Mediaarkivet, a digital archive containing more than 700 printed newspapers. See <http://www.retriever-info.com/sv/category/news-archive/>. The search was "margareta winberg kvotering kvinnor styrelse".

Thus, the magnitude of articles significantly increased, and the tone concerning a quota was sharpened at the end of 2002. Winberg's new political appointment, combined with the backing of the prime minister, strengthened the credibility of the quota threat. For the first time in history, the representation of women on the boards of listed companies began to rise consistently.

The dotted line in Figure 1 denotes 2002. In this study, we set 2002 as the baseline year since we observe data annually. This choice is reasonable for two reasons: the explicit threats were laid out at the end of 2002, and shareholders appoint new directors at an annual meeting. Since the annual meeting typically occurs in the late spring, 2003 will be the first year of treatment.⁶

The time series of the articles ends in 2003, the year when Winberg resigned. However, the investigation of the law was established by the minister of justice, Thomas Bodström, in the summer of 2005, and in June 2006 a law proposal was finished. The proposal stated that listed firms (and government-controlled limited liability companies) should have at least 40 % women on their boards by 2008; otherwise, a fine would be paid every time a new board was elected. The investigator argued that other limited liability companies also should not be subject to the law.⁷ Thus, the law proposal was consistent with the content in the previous threats made towards listed limited liability firms.

In September 2006, the Social Democratic Party lost the election and a new conservative-liberal government was formed. The new government immediately rejected the gender quota law proposal and, as depicted in Figure 1, the share of female representation halted for several years. In February 2010, both Anders Borg, the finance minister, and Per Schlingmann, the spin doctor and secretary of the leading party in the government "Nya Moderaterna", complained that progress

⁶ In the Appendix, Table A4 depicts the results if 2001 is set as the baseline year. The results do not differ substantially.

⁷ See the investigation proposal "Könsfördelningen i bolagsstyrelser" (2006) for a full description.

toward female representation was too slow (it had been steady since the Social Democrats lost the election and the law proposal was rejected), again opening up the discussion of a law (*Dagens Industri*, 2010-02-02). However, at Nya Moderaterna’s annual convention a year and a half later, party members reacted strongly and rejected any quota law (*Dagens Industri*, 2011-10-22).

Generally speaking, the development of female representation on corporate boards responds to different threat levels. However, in this paper, we will focus on the first major threats at the end of 2002 and study their effects. From a causal point of view, everything else may be an endogenous response.

III. Methodology, Data and Sampling

A. Methodology

A naïve regression population function could be written as follows:

$$(1) \quad Y_{ct} = a + \beta \text{Share_female}_{ct} + e_{ct}$$

where Y_{ct} is firm c ’s performance outcome such as operating profits/assets (ROA) at time t . It is clear that unobserved firm characteristics can determine both the variable of interest, the share of female directors on a firm’s board, and the outcome. Thus, to estimate β with no bias, we would need an instrument for the variable of interest. In addition to being strong, an instrument must be: (i) “as good as” randomly assigned and (ii) excludable, i.e., the only channel through which it operates is the endogenous variable (exclusion restriction). The “as good as” randomly assigned condition ensures a causal interpretation of the reduced form. In our setting, we could under (i) estimate the causal effect of the threat of a quota law. In a DID-setting (i) translates to parallel trends of the outcome across treatment and control groups. Thus, the reduced form in our setting becomes

$$(2) \quad Y_{clt} = \alpha + \gamma Listed_l + \lambda Post_t + \delta(Listed_l * Post_t) + \varepsilon_{clt}$$

where $Post$ is a dummy taking the value one for the period after 2002 and otherwise taking the value zero. $Listed$ is equivalently a dummy for listed firms in 2002. Under the assumption of parallel trends, δ , the parameter of the interaction, will measure the causal effect of the threat of a quota law on, for example, the share of female directors or the ROA.

If we also assume the exclusion restriction to hold, we could also write the first stage equation as the following:

$$(3) \quad Share_female_{clt} = b + \tau Listed_l + \phi Post_t + \xi(Listed_l * Post_t) + \omega_{clt},$$

and we could estimate the causal effect (a LATE) of increasing the share of women from 0 to 1 on firm performance by OLS with $\frac{\hat{\delta}}{\hat{\xi}}$.

In this paper, we suggest that it is unlikely to assume that the exclusion restriction would hold both in the setting of a law and in the setting of the threat of a law. First, imposing quotas could affect firms' recruitment procedure in numerous ways. Having to recruit women will most likely include using new expertise, networks and recruitment firms, which could have a direct effect on the outcome. Moreover, the threat of a law might signal future government interventions in general, which could influence firm actions. Further, the presence of more women on corporate boards might increase the size of the board; research suggests that board size may be important to performance through monitoring and advising (Jensen 1993; Yermack 1996). Lastly, having additional women on the board is correlated with other factors that have been found to be of importance for firm performance, such as director independence (see the survey in Adams, Hermalin and Weisbach 2010) and the size of the board. Thus, director

independence could affect firm performance, and any outsider group, not just females, would affect independence and potentially firm performance. Consequently, we view equation (3) as an interesting reduced form and one potential channel. Thus, this paper focuses on estimating the causal effect of the threat of imposing gender quotas for listed firms, and hence, parallel trends will be the major identifying assumption.

Given the large amount of disagreement in the evaluations of the Norwegian reform, we provide a battery of specification tests in this paper. First, we address compositional bias by adding industry fixed effects and thus non-parametrically control for the industry- level specific factors.⁸ Second, we acknowledge that the estimations of the standard errors are problematic in our study since treatment only changes once for one group, as discussed by Bertrand, Duflo and Mullainathan (2004) and Donald and Lang (2007). Regarding the standard errors, we begin by clustering them at the industry level, thus acknowledging not only firm correlated shocks but also industry shocks. Compared to the related literature, this is a conservative treatment of the standard errors. However, since treatment only varies once at the control – treatment group level, this might not be conservative enough. Here, we follow the Pettersson-Lidbom and Thoursie (2013) application of the results in Donald and Lang (2007). The problem is that treatment only varies at one time as at the group level l , listed and non-listed and not on the firm, c , or industry level. The error term could contain both a firm error r_{cjt} and a group - time error j_{lt} ; therefore, $\varepsilon_{cjt} = r_{cjt} + j_{lt}$. In the presence of a group time error, standard errors are biased; clustering on the firm or industry level will not help, and clustering on l cannot be done due to the low size of 2.

⁸ In Appendix Table A5, we also estimate our main model in which we leave out one industry at a time. This model is motivated by the fact that 2002 is in the aftermath of the dot-com bubble and one could worry that certain industries, for example IT or telecom, would drive our results. Our results are robust when leaving out one industry at a time.

We address the clustering problem as discussed in Moulton (1986) by aggregation. Thus, we calculate the mean for every time period for the groups listed and non-listed and estimate equation (2) on the group level (listed and non-listed). Although this addresses the Moulton (1986) problem, the error could still be serial correlated. Taking the difference between the two groups, however, we represent one time series as:

$$(4) \quad \Delta Y_t = \gamma + \delta Post_t + \Delta \mu_t,$$

where $\Delta Y_t = Y_{listed,t} - Y_{non-listed,t}$, $\gamma = \gamma_{listed} - \gamma_{non-listed}$ and $\Delta \mu_t = \mu_{listed,t} - \mu_{non-listed,t}$. With this transformation, the estimate of δ will be identical to an estimate from a fixed-effect model (where $N=2$ and $T=15$ when annual data). When estimating equation (4), we make the standard errors robust to heteroscedasticity and serial correlation by applying the Newey-West estimator.

It is straightforward to introduce two specification tests for parallel trends, as discussed by Angrist and Pischke (2009). First, we could add the leads of the independent variable *Post*. If parallel trends hold, the coefficient should come out both close to zero and statistically insignificant. We show these results graphically. Furthermore, we could add a linear trend to the specification, and if the parallel trend assumption holds true and there are no dynamic effects, then the effect should remain stable. However, since the election of board members often occurs at the annual meeting in the late spring, we could expect the effects to be smaller in 2003. We could also match on the pre-trends according to the method of synthetic control, developed in Abadie et al (2010)

Lastly, there could be other major factors affecting listed companies differently than non-listed companies. Ferreira (2015) notes the changed Norwegian Code of Practice for Corporate Governance and changed accounting rules (Norway

adopted IFRS accounting rules in 2005). Since Sweden also implemented both of these practices, we provide estimation results from a shorter window, namely, 1998-2004, which can be found in Table A6, Column (2) and (3). Our results are similar for this shorter period. In our main specifications, we make a few restrictions on data, as discussed below. The sensitiveness of the results for these restrictions can also be found in the Appendix.

B. Data

Our data consist of two data sets that have been merged. The first one is composed of all, except financial, limited liability firms' final accounts and key figures over the time period 1998-2012.⁹ To these data we add information on all individual board members in limited liability firms and the years during which they were on the board. These data contain information for the time period 1998-2012.¹⁰ Specifically, we take all board members who are on the board at some point during the given year and then compute the average share of women on the board based on these members.

From a causal point of view, anything occurring after the threat and onwards could be endogenous, including delisting. Any restriction on data before the threat is non-problematic since it is based on pre-treatment characteristics. All restrictions made below will therefore be based on characteristics in 2002. In the Appendix, we will relax our restrictions, one by one, to verify and disclose the robustness of our results. The results are found in the Appendix, Table A2.

⁹ Some firms do, however, produce two or even three accounts during one calendar year. To avoid weighting these firms more heavily, we identify their final accounts by the observation with the highest turnover in each year. Since the turnover only (weakly) increases over the fiscal year, this should leave us with the final accounts only. Notably, not all variables and measures exist for all firms in our sample.

¹⁰ The data on boards contain information for more years than 1998-2012; however, it is censored from both the top and the bottom outside the range of 1998-2012. There are no dates assigned for those that start on a board prior to 1993 or who quit after 2012. Likewise, those quitting a board prior to 1988 or after 2012 have no date recorded. Since the data on the final accounts begins in 1998, the censoring prior to 1993 does not matter. Similarly, since both the board and final accounts data end in 2012, any censoring after that point is irrelevant to this study.

We begin by creating the sampling restriction wherein we limit our analysis to all firms that are active in 2002. A non-active firm is a firm in which there is no intent to operate a normal business. Furthermore, we define treatment status based on whether a firm is listed or not in 2002. This means that we can use the number of firms as an indicator of compositional bias due to delisting.

Since non-listed firms may have a board size of 1, we limit our analysis to firms with a board size of at least 5 directors for the firms to be comparable.

Furthermore, we only consider ordinary board members as part of the board, and thus, we exclude labor union representatives, deputy directors and the likes. Although, our results are not very sensitive when also including these

While a number of other reasonable restrictions could be made, our main analysis will hinge on these restrictions. However, in the Appendix Table A3, we show results for other plausible restrictions, including restrictions on the share capital that differs across groups or public or private limited liability firms and number of employees.¹¹ These different restrictions are not driving the results.

Finally, we determine the gender of the board members through their personal identification number for all Swedish residents. Using personal numbers, we obtain exact gender information for 95.72 % of the data.¹² For non-Swedish residents, however, we rely on board members' first name only. We obtain our results by using the list of all names given to more than 10 born boys or girls in the previous year (2014) from Statistics Sweden, dropping all duplicates between the genders, and then defining the gender of the board member by checking their first name against this list. This process increased the hit rate to 98.15 %. If we could not determine the gender of a board member after this process, the board

¹¹ A public firm might have more than 200 stock owners and should have at least 500,000 SEK (approximately 60 000 USD) in share capital, whereas private limited liability firms may have as little as 50,000 SEK. Before 2005, this amount was doubly as high at 100 000 SEK. Moreover, firms need a board size of 3, whereas private firms suffice with 1 member.

¹² A regression using only those in which the gender is identified from the personal number can be found in Table A6, column 1. The results are again robust.

member's gender was coded as missing. Thus, we end up with final account data for the universe of limited liability firms in 2002 (except financial firms) for the time period 1998-2012, along with information on the boards' gender composition.

Moreover, since a firm can belong to a group of firms, we focus our analysis on the parent firm in a group. The definition of a parent firm is one that controls other firms in the group (the subsidiaries). Policies affecting a parent company thus have spillover effects on other companies in the group. Since listed companies are commonly the parent of non-listed subsidiaries, including the subsidiaries would mean a violation of SUTVA. Thus, we focus on the parent companies as the unit of observation if there exists a group and subsidiaries are not part of the main analysis. Since the parent company board is in charge of the subsidiaries, this poses no problem with respect to measuring the female director share, which is simply the share in the board of the parent. However, regarding firm performance measures such as operating profits/assets, we could either use the parent company financial statements or the group financial statements. Using the parent financial statements would generally underestimate the firm performance. However, DID estimation hinges on a parallel trends assumption, and thus we need not only this underestimation to be different across the groups but also to evolve differently over time across groups to cause a methodological problem. Therefore, using the financial statement of the parent company should not automatically pose a threat to internal validity. To verify this, we also use the financial variables from the group financial statement; our coefficient of interest is indeed unchanged. Lastly, we also redo the analysis using only parent firms that are part of a group, i.e. excluding single firms with no subsidiaries. Lastly, In the Appendix, Table A2, Column (6) also shows the results when all individual firms are treated as independent, whether they are parent firms or subsidiaries.

As is standard in the previous literature, we winsorize all financial variables at the 1 % and 99 % level. Thus, we cap all values above the 99th percentile and below the 1st percentile to the value at the 99th and 1st percentile, respectively. This procedure is conducted separately for the listed and non-listed firms. The results after alternative levels of winsorizing can be found in Table A4 and it is reassuring that point estimates are unaffected by winsorizing levels as only the precision change

The summary statistics for the listed and non-listed firms after the process of winsorizing are presented in Table 1. Panel A shows the statistics for all independent firms. That is parent firms or firms that belong to no group, i.e., firms that are independent with no subsidiaries. First, the share of female directors is approximately 14 % for the period. Second, one can note that the mean of operating profits/assets is negative for the period on average, although the median remains positive. Turning to Panel B, where we have instead used the group financial statement for the parent firms belonging to a group, we see no major differences, although both the balance sheets and the results are larger in absolute terms to some extent. In general, we observe approximately 170,000 observations, where one observation represents a parent firm or an independent firm for a given year.

[Insert Table 1 Here]

IV. Main Results

A. Graphical Evidence

We begin by inspecting the number of firms in the treatment group over time. Since we condition based on the firms being listed in 2002, it must follow that

there are (weakly) fewer firms before and after 2002. Clearly, attrition in the treatment group after 2002 might be an outcome causing survival bias when examining firm performance measures. If we find that the quota threat caused listed firms to perform better, we are worried that the worst-performing listed firms have exited. Figure 2 below shows the number of listed firms conditioned on their existence in 2002. We notice first that there is no substantial attrition in the listed group until the financial crisis in 2009. Thus, the threat does not seem to have caused a large outflow of firms from the listed group.

[Insert Figure 2 Here]

Turning to the share of female directors as an outcome, we begin by graphically inspecting the time series in Figure 3. Column 1 shows the share for the independent firms, and Column 2 shows the share for independent firms but for the matched sample where group financial statement have been used for the firms with subsidiaries. Since the match rate is high, the time series should be similar, which Figure 3 shows. Interestingly, in the years before the quota threat, we can see a slightly upward and parallel trend in both listed and non-listed firms, although non-listed firms have a higher share of female directors. After the threat, there is an extraordinary increase for listed firms, whereas the non-listed firms remain in the same approximate trend. After 2006, when the law rejected, parallel trends emerge once again. The first year's reactions are the mildest, showing some dynamic effects before stabilizing around 2006. Panel B shows the estimates as annual treatment effects, as discussed by Angrist and Pischke (2009). The estimates suggest small and mostly non-significant effects before the threat, with sharply increasing effects in the first few years after the threat, which then appear to flatten out around 2006. Although the estimates show small effects before the threat, there may be weak evidence of an increase in the share of

female board members before the threat, i.e., testing whether the effect survives when including linear treatment and control groups trend will be of interest. However, the overall pattern is consistent with a causal interpretation of the effects. The effects size seems to be approximately 8 percentage points.

[Insert Figure 3 Here]

We now turn to our main firm performance measure, operating profits divided by total assets (ROA), as used in Matsa and Miller (2013).¹³ Figure 4 of Panel A shows a rather similar downward trend until 2002. The sharp decrease in ROA due to the burst of the dot-com bubble in 2000 is visible for both groups. The dot-com bubble decline pedagogically shows the point of having a control group. Interestingly, listed parent companies have a negative ROA for the entire period, not only in the crisis following 2000. Clearly, negative ROA for such a long period cannot resemble real firm performance. Thus, it is of interest to instead use the operating profits/assets from the group financial statement if the parent belongs to a group. Column 2 of Panel A clearly shows that using the group financial statement instead of only the parent statement yields a more reliable measure of real firm performance. However, there is also a tendency for profits to decline more for the listed groups between 2000 and 2001, potentially indicating a mild Ashenfelter's dip. When analyzing the annual treatment effects in Panel B, the dip does not seem to significantly influence the results. We also note that the Lehman Brothers crisis in 2008 also yielded a sharp decline in profits and that the decrease is again somewhat larger for listed firms. It is reassuring that we do not see a pattern that the listed firms after the Lehman Brothers crisis are seeing some

¹³ Ahern and Dittmar (2012) use Tobin's Q as their measure of firm performance. To compute this metric, however, one needs the market value of the firm, which we cannot observe for the non-listed firms. We thus focus on the other commonly used firm performance measures that are available both for our treatment and control groups.

years of faster growth rates of profits/assets. Thus, the estimated effects for the threats in the period from 2003 and onwards are unlikely to merely be a convergence effect driven by the dot-com bubble in 2000. Profits increased approximately 2-4 percent of assets among listed firms after the threat, relative to the change in profits in unlisted firms in the same time period.

[Insert Figure 4 Here]

Moreover, there is an interesting correspondence between Figures 3 and 4. Both outcomes appear to be parallel before the threat. There is then a large reaction for the listed group until 2005-2006, both for the share of females and profits over assets, before a stabilization occurs.

Lastly, to address concerns about linear trends in the reduced form regarding the share of female directors and concerns that the effect might be driven by an Ashenfelter's dip, we perform a robustness check using a synthetic control group approach. Following the advice in Abadie et al. (2010), we match the dependent variable in 1998, 2000 and 2002. Both graphs show a good correspondence before 2002 and a sharp divergence afterward. The effect sizes are 8 percentage points for the share of female directors and approximately 3 percentage points for profits.¹⁴ Thus, concerns about pre-trends or dips are not critical to our results. Notably, Figure 5 also suggests that our results are not driven by functional form assumptions.

[Insert Figure 5 Here]

¹⁴ To implement Abadie et al. (2010), we collapse the data into the treatment group (in other words, all listed firms) and the remaining companies into industries. This leaves us with 57 time series, where one is the treatment group and the other 56 are the remaining companies in their respective industries. To this data we then apply the synthetic control method as in Abadie et al. (2010), where the control group is a weighted combination of the industries without the listed firms. As matching variables, we simply use the values of the dependent variable in 1998, 2000 and 2002. The exact resulting estimates of the effect can be found in Table A1 in the Appendix.

B. Main Regression Result

In Table 2 we present our main results, beginning with estimating the model outlined in equation (2), in Column 1. In Panel A we show the results when the share of female directors is the outcome. The threat of quotas caused the share of females to increase by approximately 8 percentage points, an increase of approximately 150 %. Adding industry flexible time trends in column 2 does not alter the results, thereby strengthening the indication that attrition does not cause compositional bias. In column 3, linear trends are added. Thus, our identification strategy no longer hinges on parallel trend assumption; instead, if the trend differs, it differs linearly. Since Figure 3 indicates a slightly upward trend, it is not surprising that the estimate is changed. However, it remains significant and large at approximately 4 percentage points. Notably, if the first year reaction is the mildest due to dynamic effects, which has been suggested since directors are appointed in late spring, then part of the “true” effect is controlled away when adding linear trends. Lastly, in Column 4 we present the results from estimating equation (4), i.e., using collapsed data and a time series of 15 observations to address the Moulton and serial correlation problem when estimating the standard errors. Although the standard errors double in size, the effect remains significant.

[Insert Table 2 Here]

Turning to firm performance and profits, we see in general that using the financial statements from the parent firm (Panel B) yields somewhat smaller estimates compared to using the group financial statements if the firm is the parent of a group (Panel C). However, in relation to the size of the standard errors, the effects are roughly the same. In summary, profits increased by approximately 2 – 5 percent of assets among listed firms after the threat relative to the change in profits in unlisted firms in the same time period.

Lastly, in Table 3, we restrict the sample by only using parent firms belonging to groups; this means using approximately 30,000 observations (groups) compared to approximately 170,000 in Table 2. In general, the results depicted in Table 2 remain.

[Insert Table 3 Here]

C. Additional Results

In Tables 4 and 5, we use the group's financials to construct other outcomes. We use our basic DID model, as presented in equation (2). In Column 1, Table 4, the basic estimate in which the outcome is operating profits over assets is re-tabulated. Since operating profits include depreciation and amortization, we also show the effect for the outcome EBITDA/assets in Column (2). Again, our estimate is a statistically significant EBITDA/assets increase of approximately 4 percent of assets among listed firms after the threat, relative to the change in profits in unlisted firms in the same time period. When considering only total revenue/assets, we again obtain a positive estimate, although less precisely estimated. Interestingly, labor costs/assets decrease by approximately 2 percent of assets among listed firms after the threat, relative to the change in profits in unlisted firms in the same time period. Again, this finding contrasts with that of Matsa and Miller (2013). Due to the accounting identity, an increase in profits must reflect some mixture of an increase in revenues and/or a decrease in costs. Although estimated with low precision, revenues seem to increase and labor costs to decrease. Two alternative outcomes, operating profits per employee and value added per employee, are presented in Columns (5) and (6). The results show the same sign as our other firm performance measure but are imprecisely estimated.

[Insert Table 4 Here]

[Insert Table 5 Here]

Turning to Table 5, Column (1), we confirm that the numerator of our major outcome, operating profits /assets, is positively and significantly affected by the threat. Thus, our effect is not driven by decreasing the denominator. Columns (2) and (3) show an increase in the number employed, although the figures are somewhat functionally specific because the effect becomes insignificant when using the logs instead of the levels. Columns (4)-(6) speak directly to our concern about using a gender quota law or a threat as an instrument with respect to the validity of the exclusion restriction. Column (4) shows that the female proportion of CEOs decreases by 2.5 percentage points. This result is consistent with female CEOs being recruited to corporate boards and not replaced solely by women. Columns (5) and (6) suggest that the board is also increasing in size. A back of the envelope calculation suggests that boards are expanded by one woman due to the quota threat. Thus, this finding illustrates clearly how the gender quota threat is affecting numerous potential channels that affect firm performance.

V. Conclusion

Gender quotas on corporate boards have recently received increased attention. The first quota law was adopted in Norway in December 2005. Other European countries have subsequently implemented quotas. Empirically, we know little about the effects of quotas in the board rooms on firm performance. This paper uses a credible threat of gender quotas aimed at listed firms. We find that the threat caused a substantial and rapid increase in the female board share in firms listed on the Stockholm stock exchange. The effect size was approximately 5-10 percentage points or a 100-200 percent increase. Interestingly, this increase was accompanied by an increase in measures of firm performance in the same years. We can generally reject effect sizes that are smaller than 0.005 measured as

operating profits/total assets; on average, profits increased by approximately 2-4 percent of assets among listed firms after the threat, relative to the change in profits in unlisted firms. However, increased female representation on boards did not lead to more frequent recruitment of females as CEOs, either in the short or the long run. In fact, our results indicate the opposite, which suggests that some of the female CEOs were recruited to the boards and were not always replaced by female CEOs. Moreover, labor costs decreased and sales increased, although these figures were imprecisely estimated. Our results indicate that parallel trends are a reasonable assumption, and our result is highly robust.

Although we attempt to make substantial progress with respect to the implementation of the method, we cannot rule out the possibility that, in comparison to the Norwegian studies, our conflicting results are due to differences across countries and reforms. In particular, although the Swedish quota threat was converted to a law proposal, it was never implemented due to a new government. Second, the threat increased female representation from approximately 5 to approximately 15 percent. This result was far from the level of 40 percent that was the intended goal in Norway. Clearly, the effects of gender quotas on firm performance might be a nonlinear function of female representation.

In the future, we plan to collect additional information regarding how organizational structures are affected by more female directors, in line with the questions posed by Bertrand et al. (2014). For example, will there be more females positioned in middle and top management? Will male workers and managers utilize the generous parental leave system in Sweden to a larger extent?

The standard errors are clustered at the industry level (57 clusters) errors in Column 1-4. Column 5 presents Newey-West standard errors. *p< 0.10, **p< 0.05, ***p< 0.01. Number of observations are 168,643; 168,290; and 168,405 in panel A, B and C, respectively. In Column 4, the number of observations is always 15 across all panels.

Table 3—Effect of the Threat of a Quota Law, Only Groups

Outcome	(1) Basic	(2) Compositional bias test	(3) Linear Trends	(4) Collapsed
Panel A: Effect on share of female directors, only groups				
<i>Share Female</i>	0.0869*** (0.00736)	0.0781*** (0.00679)	0.0534*** (0.00924)	0.0833*** (0.00913)
Panel B: Effect on firm performance. Group financial statement used, only groups				
<i>Profits /assets</i>	0.0344** (0.0165)	0.0303* (0.0171)	0.0386** (0.0169)	0.0354** (0.0149)
Industry trends	No	Yes	No	No
Standard errors	Clustered at industry	Clustered at industry	Clustered at industry	Newey-West

The standard errors are clustered at the industry level (57 clusters) errors in Column 1-4. Column 4 presents Newey-West standard errors. *p< 0.10, **p< 0.05, ***p< 0.01. Number of observations are 31,270 in panel A and 31,325 in panel B. In Column 4, the number of observations is always 15 across both panels.

Table 4—Other Outcomes of the Effect

	(1)	(2)	(3)	(4)	(5)	(6)
	Profits/assets	EBITDA/assets	Total revenue/assets	Labor cost/assets	Operating profits/employee	Value added/employee
<i>Estimate</i>	0.0516*** (0.0158)	0.0375** (0.0152)	0.0329 (0.0379)	-0.0225* (0.0134)	167.6 (332.7)	199.8 (331.4)

Standard errors in parentheses, Clustered at industry * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table 5—Additional Outcomes

	(1)	(2)	(3)	(4)	(5)	(6)	(7)
	Operating profits	No. employed	log(No. employed)	Female as CEO	No. on board	log(No. on board)	Average board age
<i>Estimate</i>	444628782.6*** (85660024.3)	1004.2** (386.0)	0.0586 (0.0908)	-0.0253*** (0.00757)	0.722*** (0.110)	0.213*** (0.0230)	-0.630 (0.496)

Standard errors in parentheses, Clustered at industry * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$
